LIST OF ACRONYMS

MARSYAS	Marshall System for Aerospace Simulation
MSFC	Marshall Space Flight Center
ODE	ordinary differential equation
RF–C	centrally coupled recursive feedback
RF–D	distributively coupled recursive feedback
RK–U	unified Runge-Kutta

NOMENCLATURE AND SYMBOLS

A	state gain matrix or attitude direction cosine matrix or panel area, depends on context
a	attitude control gain
aero	aerodynamic
B	input gain matrix
C_d	aerodynamic drag coefficient
cm	center of mass
cpi	center of pressure for the ith facet
d	drag
e	base of natural logarithm
$\vec{F}$	force
$f(X, t)$	mathematical function of state vector and time
G	gravitational constant
gg	gravity gradient
grav	gravity
H	height of spacecraft
I	moment of inertia matrix
i	integer variable
K	feedback gain matrix
k	loop gain
L	length of spacecraft
m	mass
n	integer variable
$\hat{n}$	unit vector normal to surface
R	orbit radius
$\vec{R}$	orbit radius vector
$\vec{r}_{cm}$	center of mass location vector
$\vec{r}_{cpi}$	center of pressure location vector for the ith facet
$\hat{r}$	unit vector in direction of orbit radius

NOMENCLATURE AND SYMBOLS (Continued)

sat	satellite
$\vec{T}$	torque
t	time
U	column matrix collection of all subsystem input vectors
u	subsystem input vector
V	orbit velocity
$\vec{V}$	orbit velocity vector
$\hat{v}$	unit vector in direction of orbit velocity
W	width of spacecraft
X	coordinate system axis or system-level state vector, depends on context
$\dot{X}$	time derivative of system-level state vector
x	coordinate system axis or subsystem state vector, depends on context
$\dot{x}$	time derivative of subsystem state vector
Y	coordinate system axis or system-level output vector, depends on context
y	coordinate system axis or subsystem output vector, depends on context
$\dot{Y}$	time derivative of system-level output vector
$\dot{y}$	time derivative of subsystem output vector
$\ddot{y}$	second time derivative of subsystem output vector
$y(0)$	initial value of $y(t)$
Z or z	axis of coordinate system
ρ	atmospheric density
ϕ	attitude angle
$\dot{\phi}$	attitude rate
ω	body rate
$\vec{\omega}$	angular velocity vector
$\dot{\vec{\omega}}$	angular velocity vector

SYSTEM SIMULATION BY RECURSIVE FEEDBACK: COUPLING A SET OF STAND-ALONE SUBSYSTEM SIMULATIONS

1. INTRODUCTION

In design and development of space systems, digital dynamic simulations have potential to reduce physical testing requirements, increase confidence in systems that cannot be tested, and ensure that subsystem requirements are not more stringent than necessary. However, simulations that address interactions of multiple disciplines and subsystems can be difficult to build. Knowledge and expertise required at the physics level, especially for high-fidelity developments, do not normally reside within one person or organization for more than one discipline or subsystem. Simulations involving individual disciplines or subsystems usually exist or can be readily constructed, and system engineers often understand the qualitative nature of interactions among them; but a means of obtaining quantitative-coupled system-level results is often unavailable. Therefore, specific practical approaches to construction of high-fidelity system-level simulations are being developed from numerous perspectives across the engineering community.

Digital dynamic simulations are often built by deriving or constructing differential-algebraic equations that define the system model and implementing algorithms to solve those equations numerically, as a single coupled set, using one of several standard or modified numerical integration methods. In some cases, software is written in a language such as FORTRAN or C to define the equations, and an existing or slightly modified ordinary differential equation (ODE) solver, perhaps a Runge-Kutta implementation, is employed to perform the integration. In other cases, an in-house development such as Marshall System for Aerospace Simulation (MARSYAS) or a commercial off-the-shelf product such as MATLAB®/SIMULINK® is used to act as a higher level facilitator of what is ultimately a mathematically similar approach.

System-level digital solution of coupled "stand-alone" dynamical simulations is a fundamentally different approach to system simulation, and fundamentally different numerical procedures are required. Recursive feedback is a conceptual method from which a family of appropriate algorithms, processes, and specific numerical procedures can be derived.

Coupled-subsystem-simulation architecture provides near complete independence of stand-alone subsimulations and naturally facilitates high fidelity and broad scope through collaboration across interfaces that can be implemented in the same physical and engineering terms that define them in the real system. Such simplicity promotes clarity of communication and ease of understanding, both of which have many positive benefits. Individual subsimulations can potentially be implemented on separate, remote, and dissimilar computational platforms, and this portends numerous advantages and possibilities as computer network capabilities improve.

2. RECURSIVE FEEDBACK ALGORITHM

2.1 Background

Brief discussions of high-fidelity, multidiscipline simulation are set forth in references 1 and 2, which resulted from association with the Structures and Dynamics Laboratory High-Fidelity Multidiscipline Simulation Development team. Reference 1 attempts to illustrate the long-term goal of multidiscipline simulation by example, while reference 2 presents the goal in a more generalized way. Reference 3 documents development of an earlier FORTRAN general purpose dynamical simulation tool (ANASIM) that uses recursive feedback as the system solution algorithm. This tool allows one to construct a simulation by choosing system elements from a menu and specifying connections (signal flow) among them. The elements (integrators, summers, limiters, etc.) are, in effect, small stand-alone subsimulations. A definition and explanation of the method is presented, and an analytical demonstration of response computation for a first-order, single-state, constant-coefficient system with a step input is included. The demonstration, or mathematical "show that," is accomplished through symbolic algebraic application of the algorithm followed by direct comparison of results with the exact closed-form solution.

In reference 4, the method is analytically demonstrated for some simple examples within a variety of system classes. The first is the n-dimensional linear constant-coefficient case defined by the matrix vector equation $\dot{x}(t) = Ax(t) + Bu(t)$, which is a standard state-variable form. The remaining four are scalar (single state) cases that include two nonlinear, continuous cases; a linear time-varying coefficient case; and a numerically demonstrated case involving a state-dependent discontinuity and an algebraic loop. The analyses of reference 4 provide additional mathematical insights into the process, particularly with respect to convergence.

Analysis of the method is extended to coupling of stand-alone subsystems in references 5 and 6. Reference 5 mathematically defines and analytically demonstrates recursive feedback for generation of responses from a generic linear-dynamic system composed of internally inaccessible subsystems, and reference 6 continues beyond to include subsystems that have potential to produce algebraic loops at the system level because they contain direct feed-through of input.

References 5 and 6 specifically address process convergence and essentially guarantee that recursive feedback can be used as a system-level solution algorithm for simulation of linear systems composed of coupled stand-alone subsystems for a broad range of ordinary circumstances. Combined with the analyses of reference 4 and experience associated with ANASIM (ref. 3), it seems reasonable to expect that the method can be dependably applied to nonlinear system simulation. Only experience, and perhaps more analysis, will determine the effectiveness of extrapolation to these supposedly more stringent conditions.

2.2 Concept

Referring to figure 1, the subsystems are represented by independent, self-contained, time-domain, dynamical simulations that can be commanded to run from a given set of initial conditions over a predetermined segment of time when provided with input signals as functions of time over that interval. In general, the time segment, also referred to as a convergence interval, is short compared with the total desired system simulation duration, but may be significantly larger than the integration step size associated with a typical subsimulation. For each new stage of recursion, subsystem input signals are computed using original system-level input signals summed with system-level feedback (coupling) signals generated at the current stage. New (next recursion stage) subsystem responses are computed using new subsystem input signals in conjunction with the same (original) initial conditions. The process continues recursively until convergence is achieved. After convergence, initial conditions are replaced with final conditions and the process is restarted for the next segment of time. System response over the total desired duration of the simulation is the concatenated set of combined subsystem responses over many time segments.

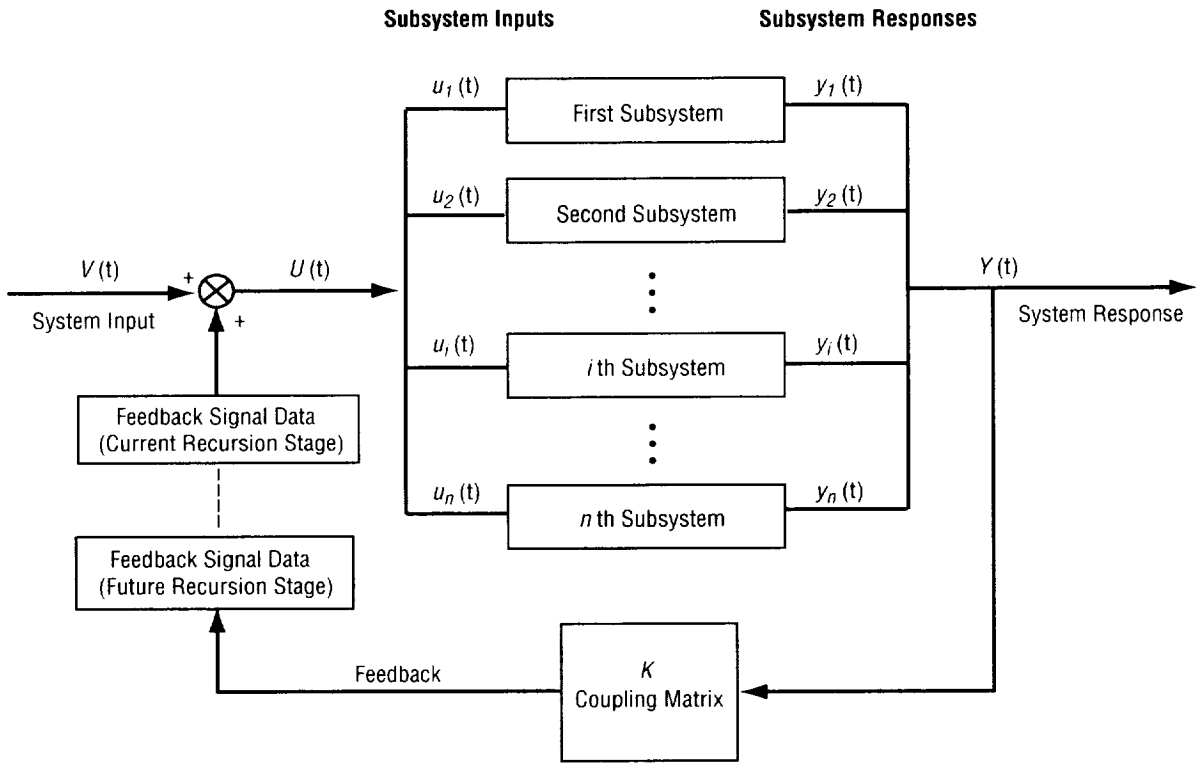

Figure 1. Schematic of recursive feedback process.

2.3 Insights for Specific Design

Because figure 1 describes a system of considerable generality whose complexity for a specific case can range from simple to great, further clarification of the process seems appropriate. The simplest "system" could arguably be a single integrator in the forward path, a constant multiplier (gain) in the backward (feedback) path, no (zero) system-level input, and a nonzero initial condition on the output. In that case, there is one linear subsystem, and that subsystem is a single integrator. The output function is the integral of the subsystem-level input function with respect to time, and can be generated independently and directly by simply computing the area under the input curve over the time interval of interest (convergence interval) and adding the initial condition. The coupling matrix becomes a scalar (value of the loop gain), and actually represents direct feedback rather than coupling. The process, however, does not explicitly make such a distinction, nor does it need to. The summing junction becomes moot since there is no system-level input. The recursive transfer point remains as depicted in figure 1, but does not exist in the analog system to be digitally simulated. The scalar differential equation that models the analog system is $\dot{y}(t) = ky(t)$, where t is time and k is the loop gain, and the exact closed-form solution for the output response is given by the exponential function

$$y(t) = y(0)\,[e^{kt}] \ , \tag{1}$$

where $y(0)$ represents the initial value of the output $y(t)$.

Applying recursive feedback to this system, the output is first computed as a function of time over the convergence interval as if there were no (zero) feedback. This function is referred to as the stage zero output response. Because the system input function is also zero in this case, the response is a constant function of time symbolically represented by

$$y^{(0)}(t) = y(0) \ , \tag{2}$$

where the parenthesized superscript is the stage index. Next, the stage zero feedback function is computed by multiplying the stage zero output response function by the loop gain k. After "moving" the feedback function data across the recursive transfer point and summing it with the system-level input function (zero), it becomes the stage one subsystem input function. Stage one response can now be computed by numerical integration (area under the curve) of the new (stage one) input function while applying the original initial condition $y(0)$. A symbolic representation of the result is

$$y^{(1)}(t) = y(0)[1 + kt] \ . \tag{3}$$

Repeating the process, symbolic representation of the stage two result is

$$y^{(2)}(t) = y(0)[1 + kt + \frac{(kt)^2}{2!}] \ . \tag{4}$$

By induction, the nth stage response is given by

$$y^{(n)}(t) = y(0)\left[1 + kt + \frac{(kt)^2}{2!} + \cdots + \frac{(kt)^n}{n!}\right] . \tag{5}$$

Clearly, if sufficiently continued, the recursive process yields a solution that approaches the exact solution $y(t) = y(0)[e^{kt}]$. In theory, the time interval (convergence interval) for this case can be as long as desired; in practice, it must be restricted because of numerical integration and roundoff errors. As mentioned earlier, system response over the problem duration is represented by a concatenation of responses over as many convergence intervals as needed, and a single convergence interval is measured in multiple integration steps. It is noted that each recursion stage improves accuracy of the approximate system response by adding the next higher order term in a series expansion of the exact system response. This type of behavior is seen in all of the linear system analyses of references 3–6. For the nonlinear systems of reference 4, each recursion stage adds higher order terms; but for a given number of correct terms in the series expansion, a greater number of recursion stages is required. For these systems, the convergence interval cannot be arbitrarily long, even without integration and roundoff errors, and the degree of restriction required depends on the initial condition.

Considering the system in figure 1 in its more general context, the off-diagonal elements of the coupling matrix represent the means by which output from one subsystem is processed and channeled to construct input for another. Because direct dependence of the input to any subsystem on the output of that same subsystem is likely to have been handled internally, the elements on the diagonal are likely to be zero; although, as demonstrated, the method does not require this to be the case. In development of a system simulation by coupling of subsystem simulations, the nature of the coupling matrix is, to a large degree, a design choice.

Consider, for example, the "system" to be an undamped oscillator governed by the scalar differential equation $\ddot{y}(t) + \omega^2 y(t) = 0$, where ω is the frequency of oscillation. A simulation of this system by recursive feedback can be set up in at least two very different ways. One design possibility is to define a single subsystem, best described as a double integrator, or two single integrators in series. The output function of the subsystem is determined by integrating its input function twice. The coupling matrix once again degenerates to a scalar constant, $-\omega^2$, and the system input function is zero. Assuming a nonzero initial condition $y(0)$ on the output (displacement), application of recursive feedback to this system results in a truncated series definition of $y(t)$, and at the nth recursion stage, a symbolic representation is

$$y^{(n)}(t) = y(0)\left[1 - \omega^2\frac{t^2}{2!} + \omega^4\frac{t^4}{4!} + \cdots + (-1)^n\omega^{2n}\frac{t^{2n}}{(2n)!}\right] . \tag{6}$$

Then for a sufficiently large number of recursion stages, the approximate solution approaches the exact solution $y(t) = y(0)[\cos\omega t]$. Once again the number of terms in the series corresponds directly to the number of recursion stages, but the order of the series with respect to time is twice the number of recursion stages.

In contrast, a second design possibility is to define two subsystems that are both single integrators. The governing differential equation is now given by the two-dimensional matrix-vector equation

$$\dot{Y}(t) = KY(t) \ , \tag{7}$$

the coupling matrix is given by

$$K = \begin{bmatrix} 0 & 1 \\ -\omega^2 & 0 \end{bmatrix} , \tag{8}$$

and the output function is given by

$$Y(t) = \begin{bmatrix} y_1(t) \\ y_2(t) \end{bmatrix} , \tag{9}$$

where $y_1(t)$ represents displacement and $y_2(t)$ represents velocity. Application of recursive feedback to this system results in a truncated series definition of $Y(t)$. At the nth recursion stage, the numerically computed approximate system response function is symbolically represented by

$$Y^{(n)}(t) = \left[I + Kt + K^2 \frac{t^2}{2!} + \cdots + K^n \frac{t^n}{n!} \right] Y(0) \ . \tag{10}$$

Again, each numerical recursion stage, in effect, adds one term to the truncated series approximation of the exact solution.

For the two-subsystem, twin-integrator approach, it takes two recursion stages to reach the same order of approximation in time that was reached in one stage with the single-subsystem, double-integrator approach. However, the twin integrators represent independent operations that can be performed in parallel, while the double integrator represents two operations that must be performed in series. In the double integrator case, velocity, $\dot{y}(t)$, does not appear at the system level, only one function crosses the recursive transfer point, and only one function is checked for convergence. In the twin integrator case, velocity, $y_2(t)$, appears at the system level, both $y_1(t)$ and $y_2(t)$ cross the recursive transfer point, and both functions can be checked for convergence at the system level. Clearly, in a more complex situation, the relative merits of these approaches become simulation design and performance issues.

For the broader range of systems contained within the framework of figure 1, the nature of the coupling matrix is a function of many possible simulation design choices. In its most basic form, a coupler would simply route signals from one subsystem to another without modifying them. In its most complex form, it could become a multidimensioned nonlinear operator as well. Typical coupler functions are likely to be coordinate transformations, gain multiplications, interpolations, and other data modification or routing tasks that must be performed to make proper interface connections among a set of predefined or existing subsimulations.

As implied by the double integrator example (when viewed as two single integrators in series), it is also possible to distribute the coupling functions throughout the system. In a particular situation, one might choose to view several subsimulations as a combined set if the nature of the coupling among them is such that an output response can be determined from an input function without necessity for recursion (there is no feedback loop internal to the set). In that case, processing information as it is transferred from one set member to another represents a coupling function that does not reside as an element of a centralized coupling matrix. Utilizing the powers of block diagram algebra or signal flow analysis, many arrangements of subsystems and couplers may be possible for representation of a given system. Such design freedom can have a significant impact on the configuration, performance, and efficiency of the simulation.

To be of practical value in dynamical systems simulation, the recursive feedback concept must be applicable to nonlinear models. The "guarantees" and insights that come with analyses like that of reference 6 are weakened at best and totally lost at worst without the linear model assumption. However, one does have a guarantee of solution existence and uniqueness for a broad range of sufficiently well-behaved nonlinear systems (ref. 7). A converged recursive feedback process is indicative of a solution with exception of questions concerning discretization errors, roundoff errors, inappropriate tolerances, etc. The potential for convergence can normally be improved by reducing the length of the convergence interval, not unlike reducing integration stepsize in a conventional situation when satisfactory results are not achieved.

3. EXAMPLE SYSTEM

The example system is designed to be simple but to reflect real possibilities. It consists of a satellite that has an attitude control system, is in low-Earth orbit, and is experiencing aerodynamic effects in addition to gravitational effects. The spacecraft is idealized as a rigid body of rectangular "box" shape, illustrated in figure 2. The center of mass is offset from the geometric center by a small amount in all three axes, and moments of inertia are such that there are two large but somewhat unequal principal values, while the third principal value is much smaller. The principal axes are normal to the box surfaces so that all cross products of inertia are zero. The models are based on constant density atmosphere, spherical Earth (inverse square) gravity, and linear attitude control for small motion about an inertial reference. Attitude control can be partially or totally removed so that the body is allowed to tumble under the influence of gravity and aerodynamics. Gravitational, aerodynamic, and control torques affect the rotational dynamics of the rigid body, while gravitational and aerodynamic forces affect the translational dynamics. Both translational and rotational dynamics affect aerodynamic forces and torques, so a feedback loop is apparent. This example falls in the general category of nonlinear, continuous systems.

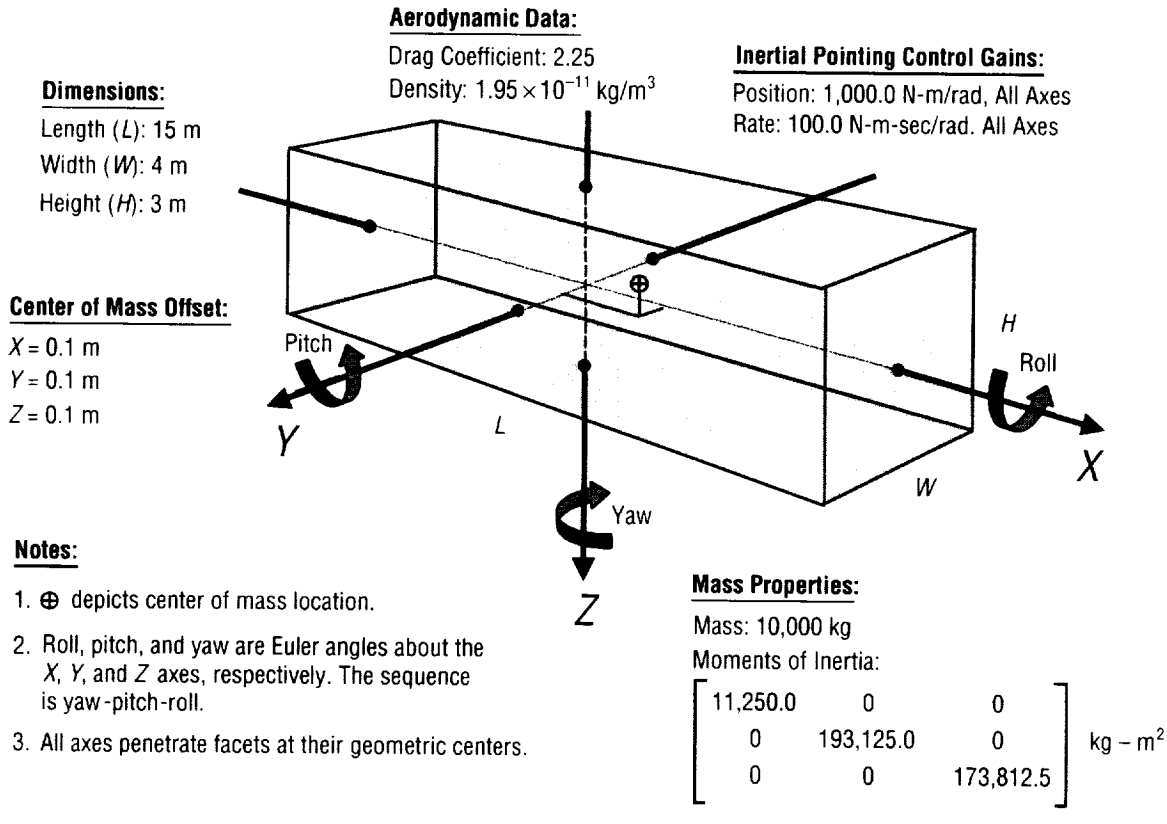

Figure 2. Spacecraft properties and geometric body-fixed coordinate system.

4. MATHEMATICAL MODELS

4.1 Orbit Dynamics

The orbit dynamics is modeled by

$$m_{\text{sat}} \frac{d^2\vec{\text{R}}}{dt^2} = \vec{\text{F}}_{\text{grav}} + \vec{\text{F}}_{\text{aero}} \quad , \tag{11}$$

where

$$\vec{\text{F}}_{\text{grav}} = -\frac{Gm_{\text{Earth}}m_{\text{sat}}}{R^3}\vec{\text{R}} \quad . \tag{12}$$

G is the universal gravitational constant, m_{Earth} and m_{sat} are masses of the Earth and the satellite. $\vec{\text{R}}$, the orbit radius vector, extends from the center of the Earth to the center of mass of the satellite and is expressed in an Earth-centered reference frame that is defined to be nonrotating and assumed to be nonaccelerating. $\vec{\text{F}}_{\text{aero}}$, the aerodynamic force, is derived from an aerodynamics model to be discussed later. This development, as well as the attitude dynamics development, is standard and of the general type found in many dynamics texts such as reference 8.

4.2 Attitude Dynamics

The rotational dynamics is modeled as a rigid body by

$$I\dot{\vec{\omega}} + \vec{\omega} \times I\vec{\omega} = \vec{\text{T}}_{\text{control}} + \vec{\text{T}}_{\text{gg}} + \vec{\text{T}}_{\text{aero}} \quad , \tag{13}$$

where I is the moment of inertia matrix, $\vec{\omega}$ is the angular velocity vector, $\vec{\text{T}}_{\text{gg}}$, is gravity gradient torque, $\vec{\text{T}}_{\text{aero}}$ is aerodynamic torque, and all quantities are expressed in a body-fixed coordinate system whose origin is at the center of mass.

The attitude is defined by a set of Euler angles $\left[\phi_x, \phi_y, \phi_z\right]$ that indicate angles traversed by a hypothetical reference frame as it is rotated from coincidence with an inertial (nonrotating) attitude reference frame to coincidence with the body frame using three single-axis rotations in a z-y-x sequence. The instantaneous Euler angle rates are then related to body rates by

$$\begin{bmatrix} \dot{\phi}_x \\ \dot{\phi}_y \\ \dot{\phi}_z \end{bmatrix} = \begin{bmatrix} 1 & \sin\phi_x \tan\phi_y & \cos\phi_x \tan\phi_y \\ 0 & \cos\phi_x & -\sin\phi_x \\ 0 & \sin\phi_x \sec\phi_y & \cos\phi_x \sec\phi_y \end{bmatrix} \begin{bmatrix} \omega_x \\ \omega_y \\ \omega_z \end{bmatrix} \quad . \tag{14}$$

Although this particular formulation has a singularity at $\phi_y = \pm\pi/2$, it is valid except at that point, and can serve as the basis for a model if an adequate neighborhood of that point is avoided.

A vector expressed in inertial coordinates is transformed to body coordinates through multiplication of the corresponding column of inertial components by the direction cosine matrix

$$A = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos\phi_x & \sin\phi_x \\ 0 & -\sin\phi_x & \cos\phi_x \end{bmatrix} \begin{bmatrix} \cos\phi_y & 0 & -\sin\phi_y \\ 0 & 1 & 0 \\ \sin\phi_y & 0 & \cos\phi_y \end{bmatrix} \begin{bmatrix} \cos\phi_z & \sin\phi_z & 0 \\ -\sin\phi_z & \cos\phi_z & 0 \\ 0 & 0 & 1 \end{bmatrix}. \tag{15}$$

The attitude control system is modeled by

$$-\bar{T}_{\text{control}} \Leftarrow \begin{bmatrix} a_{0x}\phi_x + a_{1x}\omega_x \\ a_{0y}\phi_y + a_{1y}\omega_y \\ a_{0z}\phi_z + a_{1z}\omega_z \end{bmatrix}, \tag{16}$$

where ϕ, ω, and a are associated with attitude angles, body rates, and control gains, respectively, and the subscripts are self-explanatory.

The gravity gradient torque is modeled by[9]

$$\bar{T}_{gg} = \frac{Gm_{\text{Earth}}}{R^3}\hat{r} \times I \cdot \hat{r}, \tag{17}$$

where $\hat{r}$ is a unit vector corresponding to $\bar{R}$ expressed in body coordinates.

4.3 Aerodynamics

A box with six rectangular side panels (facets) defines the satellite shape (fig. 2). Aerodynamic drag forces associated with the ith panel are approximated empirically by the formula[9]

$$\bar{F}_i = \begin{cases} -\frac{1}{2}\rho V^2 C_d A_i (\hat{n}_i \cdot \hat{v})\hat{v} & \text{if} \quad \hat{n} \cdot \hat{v} \geq 0 \\ 0 & \text{if} \quad \hat{n} \cdot \hat{v} \leq 0 \end{cases}, \tag{18}$$

where ρ is atmospheric density, V is velocity magnitude relative to the atmosphere, C_d is a drag coefficient, A is panel area, $\hat{n}$ is a unit vector normal to the panel and directed outward from the box, and $\hat{v}$ is a unit vector corresponding to $\vec{V}$. If rotation of the Earth is neglected, no distinction between relative and absolute velocity need be made. The total aerodynamic force is given by

$$\vec{F} = \sum_{i=1}^{6} \vec{F}_i \quad . \tag{19}$$

While the vector relationships of equations (18) and (19) are independent of any particular coordinate system, the most convenient choice is a body-fixed "geometric" coordinate system (fig. 2) whose origin and axes are defined from geometry (shape) considerations alone. The aerodynamic force as used in equation (11) is most appropriately expressed in inertial coordinates. Appropriate coordinate transformation depends on the matrix A, defined by equation (15), and on the orientation of the body frame with respect to the geometric frame. As illustrated in figure 3, the axes of the body frame are not rotated with respect to the geometric frame, so the relevant transformation is identity.

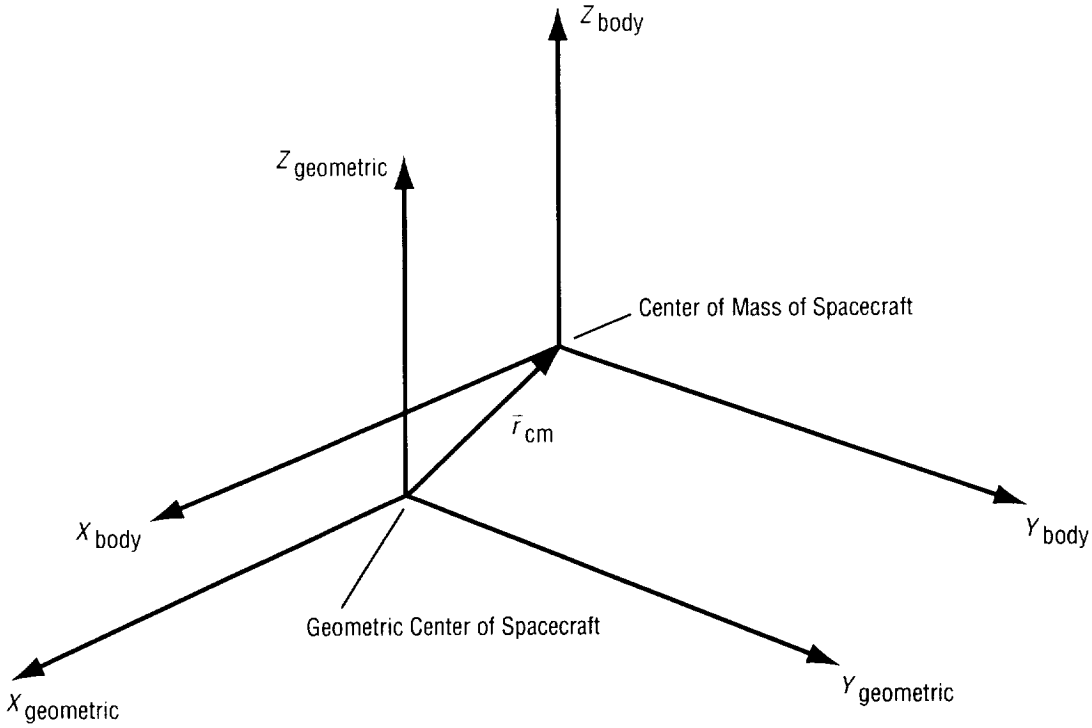

Figure 3. Relationship of body frame to geometric frame.

The total aerodynamic torque about the origin of the geometric frame is calculated from six contributing components and is given by

$$\bar{T} = \sum_{i=1}^{6} \bar{r}_{cpi} \times \bar{F}_i \quad , \tag{20}$$

where $\bar{r}_{cpi}$ is a vector from the origin of the geometric coordinate system to the center of pressure for the ith facet. The total aerodynamic torque about the center of mass of the spacecraft, as used in equation (13), is given by

$$\bar{T}_{cm} = \vec{T} - (\bar{r}_{cm} \times \bar{F}) \quad . \tag{21}$$

where $\bar{r}_{cm}$ is a vector from the origin of the geometric coordinate system to the center of mass (fig. 3).

5. SUBSYSTEM SIMULATIONS

Simulations for each of the three subsystems (orbit dynamics, attitude dynamics, and aerodynamics) have been constructed as functionally separate entities, although they are implemented as parts of one single FORTRAN computer program. The attitude and orbit dynamics simulations both have 3 degrees of freedom, and each has its own separate implementation of a Runge-Kutta numerical integration process. In both cases, the three second-order differential equations have been rearranged to six first-order equations for interface with the integration algorithm. The aerodynamics simulation has no integration process because the model is purely logical-algebraic. All three simulations are "stand-alone" because each, in principle, is capable of producing output signals (functions of time) from input signals and initial conditions. Initial conditions, of course, do not apply to the logical-algebraic aerodynamic simulation. Input and output signals are represented by a sequence of linearly connected points equally spaced in time. Additional points are obtained through interpolation by each simulation if needed.

The orbit dynamics simulation input signal is aerodynamic force, and output signals are orbit radius and velocity vectors. The model, defined by equations (11) and (12), considers a point mass, inverse square gravity, and an external force (aerodynamics) that is an arbitrary but known function of time. All orbit dynamics simulation variables are referenced to an Earth-centered inertial coordinate system.

The attitude dynamics model input signals are the orbit radius vector expressed in inertial coordinates, and aerodynamic torque expressed in body coordinates. Output signals are body rates and attitude angles. The model, defined by equations (13)–(17), considers rotational motion of a rigid body, gravity gradient torque, attitude control system torque, and an external torque (aerodynamics) that is an arbitrary but known function of time.

The aerodynamics simulation input signals are orbit radius vector in inertial coordinates and orbit velocity vector in body coordinates. Output signals are aerodynamic force and torque expressed in geometric coordinates. The model is logical-algebraic and is defined by equations (18)–(21).

6. SYSTEM SIMULATIONS

Three system simulations have been constructed. The first simulation uses a centralized coupling implementation of recursive feedback, while the second simulation uses a distributed coupling implementation. The third simulation uses a conventional first-order, single-equation set approach and is the standard against which the recursive feedback approaches are compared.

By design, the function of a coupler is to perform coordinate transformations or other types of data conversions needed to make consistent, correct connections among the subsystem simulations. A single coupler can perform all coupling functions from one central location, or a set of couplers that perform less extensive functions can be distributed throughout the system. Coupling signals, like input and output signals, are represented by a sequence of points equally spaced in time.

Figures 4 and 5 illustrate the centrally coupled system simulation. The subsimulations represent independent processes that can, in principle, be executed in parallel over the timespan of each convergence interval. Because the primary purpose is to investigate functionality rather than efficiency, no attempt has been made to use more than one processor in the single-computer FORTRAN implementation. Therefore, the parallel computation advantage is lost, and quantitative comparison of efficiency with the other simulations is not possible.

Figure 6 illustrates the distributively coupled system simulation. Before applying the idea of recursive feedback, the subsystems have been arranged so that, to the extent possible, feedback is minimized. Because there is an information loop that ultimately must be closed, it is not possible to completely eliminate feedback. The subsimulations are identical to those of the centrally coupled system, but the system-level numerical process is substantially affected because, among other things, the number of scalar signal paths that cross the recursive transfer point has changed. This simulation was developed in part because the centrally coupled simulation, developed first, is noticeably slower than the standard method benchmark. More importantly, it serves to confirm functionality of the different coupling architectures.

The conventional simulation is implemented from the combined set of equations that define the subsystem models. They have been collected and rearranged, by hand, to a single set of 12 first-order differential equations, an arrangement sometimes called a "state variables" approach to system formulation. In that context, the state vector is defined as

$$X = \left[R \mid V \mid \phi \mid \omega \right]^T \quad , \tag{22}$$

where R, V, ϕ, and ω are three-element row vectors representing orbit radius, velocity, Euler angles, and body rates. The system differential equations can now be represented as a first-order set by

$$\dot{X} = f(X, t) \quad , \tag{23}$$

where time has been explicitly included only for completeness of the form. In the current simulation, time is only implicitly involved, because there are no system forces or torques that are explicit functions of time. A fourth-order Runge-Kutta numerical integration algorithm specifically designed to solve systems in the form of equation (13) is employed to propagate the system responses.

All system and subsystem simulations were specially developed for this project. They are written in FORTRAN, all data were generated on the TD55/eds2 UNIX platform at Marshall Space Flight Center (MSFC). Plots were originally produced with an in-house program (developed by Warren Adams, TD55, MSFC) on the same machine. Plot images were migrated to a Windows desktop PC for publication. A full complement of plots is included in appendix A, and listings of the simulation programs are included in appendix B.

7. NUMERICAL RESULTS

7.1 Run Case Definitions

All data cases simulate motion of the same spacecraft starting from the same orbit and attitude related initial conditions. The orbit is initialized so that in the absence of aerodynamic drag it would be circular at an altitude of 300 km and an inclination of 30 deg. The initialization point is in the X–Z plane of the coordinate system shown in figure 7. Spacecraft mass properties, dimensions, and control gains are given in figure 2. Initial attitude angles and body rates are zero. Other data constants and physical constants are identified in the computer listings. Case variations are developed from three attitude control system configurations and three simulation methods resulting in a nine-element run matrix. The attitude control configurations are listed as follows:

(1) Full inertial control
(2) Partial inertial (two-axis) control
(3) No control (tumble).

Case numbers correspond directly to the control system configuration list entry numbers, and method variations are associated with each case. The simulation methods are:

(1) Centrally coupled recursive feedback (RF–C)
(2) Distributively coupled recursive feedback (RF–D)
(3) Conventional (unified) Runge-Kutta (RK–U).

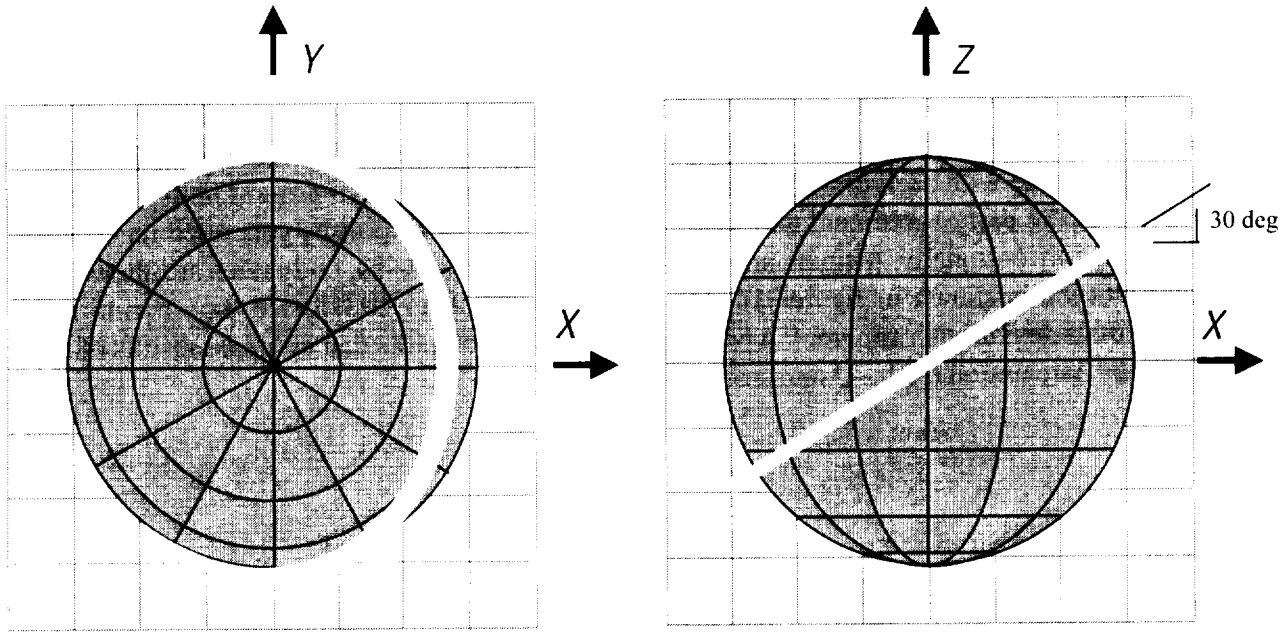

Figure 7. Inertial coordinate system/initial orbit plane geometry.

Numerical algorithm parameter settings were the same for all cases. Both recursive methods used five sample points per convergence interval (including both end points), and the interval length was 0.4 sec. Relative (normalized) and absolute convergence tolerances were both 10^{-12} for the RF–C and 10^{-14} for the RF–D. The orbit and attitude subsimulations both used a fourth-order Runge-Kutta algorithm with a step size of 0.1 sec, while the aerodynamics subsimulation computed aerodynamic effects at a 0.1-sec sample interval. The conventional simulation used the same Runge-Kutta algorithm with a step size of 0.1 sec.

Results for all possible (nine) combinations of control system configuration and solution methods were generated. For case 1, in the absence of any well-defined requirement, a set of control system gains was chosen that produce reasonable (small angle) attitude dynamics responses. For case 2, the Z-axis control gains were set to zero; and for case 3, all control gains were set to zero. Simulation responses have been generated for 60,000 sec of problem time using all solution approaches for all cases.

7.2 Response Comparisons

The responses for case 1 (full control) are identical over the full 60,000-sec duration of the simulation runs for all solution approaches (RF–C, RF–D, and RK–U). Appendix A.1 contains 108 plots that compare RF–D results to conventional RK–U results for case 1. Radius, velocity, attitude angles, body rates, aerodynamic forces, aerodynamic torques, and altitude are shown as functions of time. The general format of the appendix presentation is to show each response over time intervals of 0–20,000, 20,000–40,000, and 40,000–60,000 sec, and additionally, to show some selected plots that cover smaller time intervals of particular interest.

The responses for case 2 (two-axis control) are, like case 1, identical over the full 60,000-sec duration of the simulation runs for all solution approaches. Appendix A.2 contains 92 plots that compare RF–D results to conventional RK–U results for case 2. As in the appendix presentation for case 1, radius, velocity, attitude angles, body rates, aerodynamic forces, aerodynamic torques, and altitude are shown as functions of time, and the presentation format is also similar to that used for case 1.

For case 3 (tumble), the RF–C, RF–D, and RK–U simulation responses all agree for approximately 45,000 sec of the duration; after that, the RF–C and RF–D responses begin to diverge from the RK–U while they continue to agree with each other for the full 60,000 sec. Figures 8–16 present plots selected specifically to illustrate the early agreement and subsequent deviation of responses generated recursively from those generated conventionally. Attitude angles are shown in figures 8–10, body rates are shown in figures 11–13, and altitude is shown in figures 14–16. Only the 40,000- to 60,000-sec time period is covered because no earlier deviation is apparent. Appendix A.3 contains 60 plots that compare results of the RF–D approach to the conventional RK–U approach for this case.

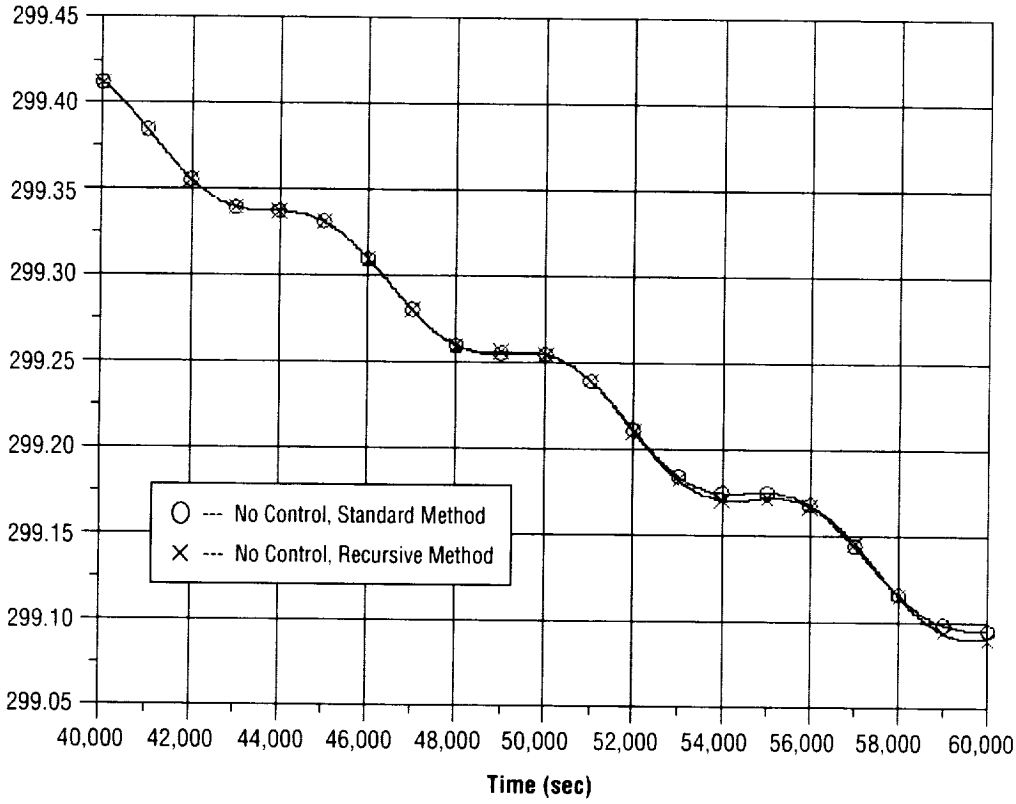

Figure 14. Case 3, altitude, first time segment (km).

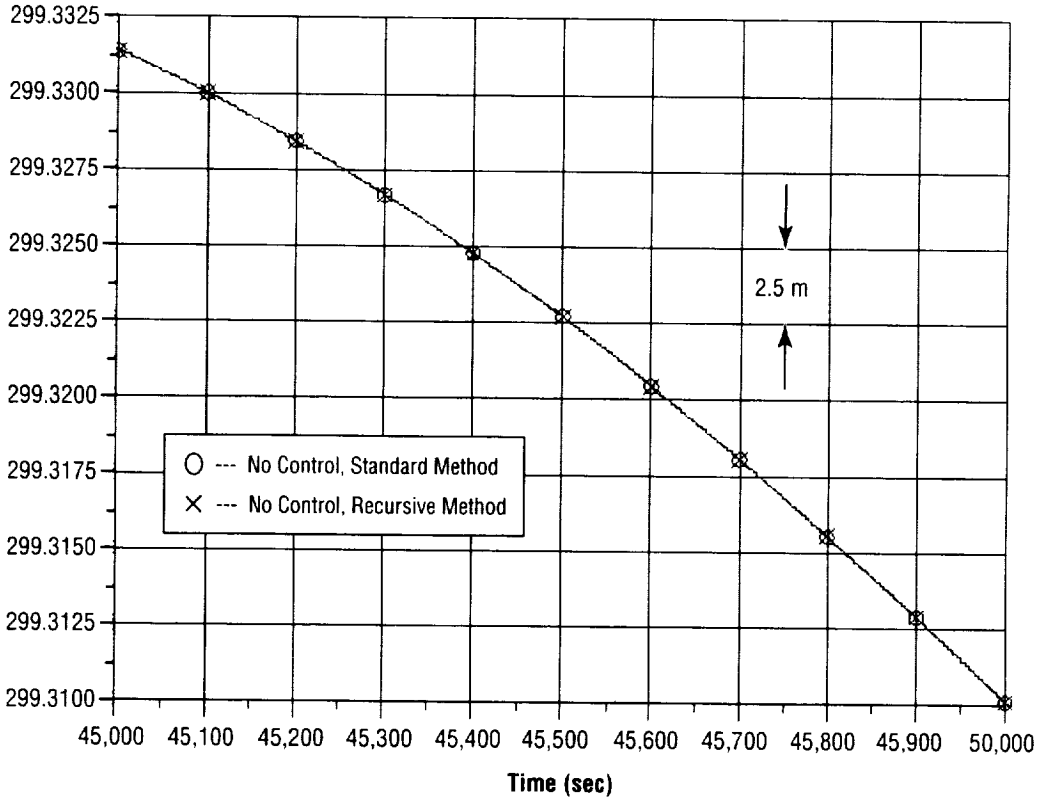

Figure 15. Case 3, altitude, second time segment (km).

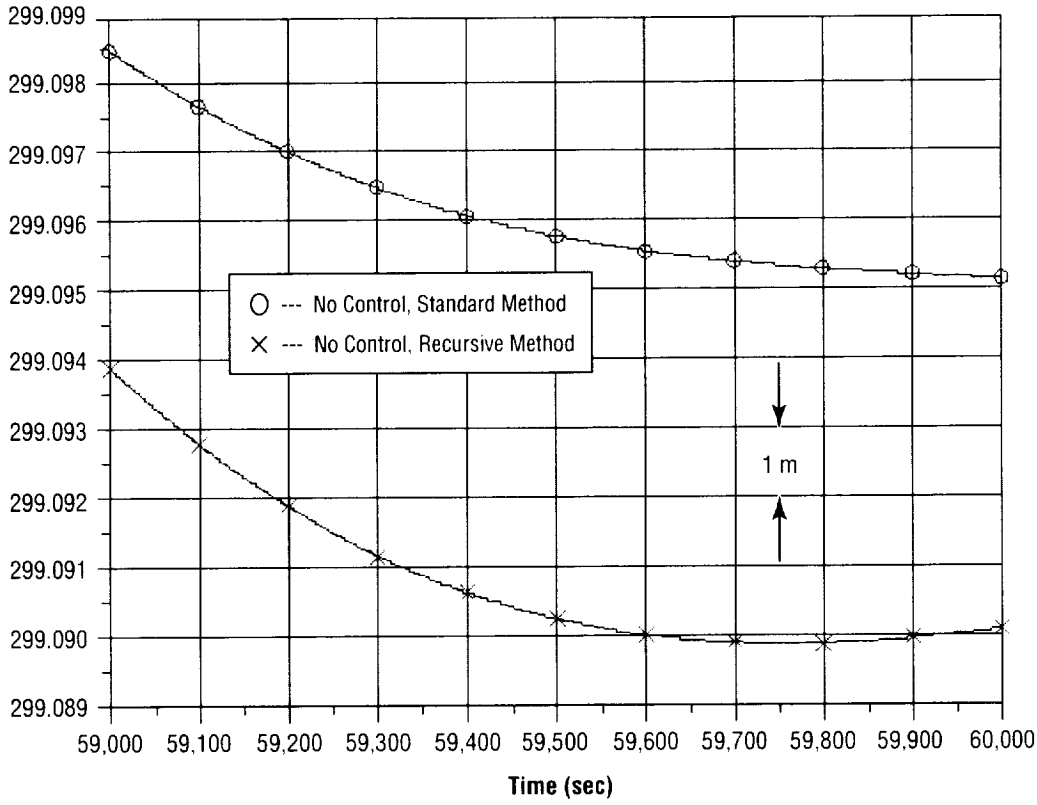

Figure 16. Case 3, altitude, third time segment (km).

Altitude results for all control system configurations and two solution methods (RF–D and RK–U) are superposed in figures 17–19. The main point of illustration is the variation in orbit decay rate as a function of attitude control. Figure 17 shows the full 60,000-sec run duration, while figures 18 and 19 show shorter time segments taken near the end of the run. Figures 17–19 illustrate again the agreement of recursive and conventional solution methods for cases 1 and 2, while showing the method-induced deviation apparent in case 3, the no control (tumble) case.

Appendix A.4 contains 42 plots that compare results from the two recursive approaches (RF–C and RF–D) to each other for all three cases. These plots are presented primarily for completeness since, for all practical purposes, the responses are identical for both methods over the full 60,000-sec duration of the simulation runs.

8. PERFORMANCE

The numerical results presented in figures 8–19 and in appendix A very clearly confirm that coupling of discipline-oriented subsimulations by recursive feedback can be used successfully as an architecture and solution approach to simulation of the example system. In cases 1 and 2, 60,000 sec of run time is achieved with no significant deviation of results. In case 3, deviation begins at approximately 45,000 sec. The earlier deviation of case 3 is attributed primarily to linear interpolation of aerodynamic forces and torques over the subsimulation integration step size in the recursive (RF–C and RF–D) implementations, while aerodynamic computations are made at points internal to the integration interval in the unified (RK–U) implementation. Improvement could likely be found through a more sophisticated interpolation method, a shorter convergence interval, or an increased number of points per convergence interval for signal definition. It must be remembered, however, that eventual disagreement of dynamic simulations driven by different numerical processes is always expected.

The results also confirm that the location and distribution of coupling functions, while partially defined by the fundamental nature of the subsystem interactions, can be part of the simulation design and can have a significant affect on performance. For the current example, the convergence interval length (0.4 sec) and the number of points per convergence interval (five) are the same for both recursive approaches, and the accompanying subsimulations as well as the conventional simulation all use the same integration step size (0.1 sec). Convergence error tolerances were in the range of 10^{-12} to 10^{-14} for the recursive methods. Typical reported processor utilization times for the RF–C, and RF–D simulations are approximately 1,200 and 800 sec, respectively, while the RK–U time is approximately 200 sec.

As mentioned earlier, the potential parallel computation advantage of the RF–C simulation is lost because of the particular single-computer FORTRAN implementation. Given that fact, the RF–D (fig. 6) simulation is understandably faster than the RF–C (fig. 4) because the amount of data being processed and checked to confirm or deny convergence at the recursive transfer point is significantly less. The speed of the RF–C simulation would be increased if the subsimulations were actually run in parallel. The possibility for running subsimulations in parallel does not exist for the RF–D simulation because the process design requires them to be run sequentially. In either recursive method, output from the last stage of the process is used to compare against the previous stage for confirmation of convergence. In the conventional method, no active control of error is currently present, and inclusion of any such mechanism would require additional computation; conversely, predetermination of the number of recursion stages and elimination of the convergence check could significantly reduce the computation load for either recursive method. For the current example, the maximum number of recursion stages is typically three, one of which could arguably be said to serve no purpose other than to confirm satisfaction of error tolerances. As the number of recursion stages increases, the extra time required for the confirmation stage becomes less significant in a relative sense, but elimination of the checking process entirely would save time at every stage.

None of the current simulations were constructed with emphasis on efficiency. After correctness, programmer convenience and listing readability were the next higher priority considerations. It is believed that many strengths of recursively coupled subsimulations architecture lie in areas other than computational efficiency and those strengths may sometimes be well afforded at considerable expense.

9. IMMEDIATE FUTURE DEVELOPMENT

More analytical investigation and development are appropriate. Analyses that investigate error sources, error propagation, computational efficiency, and stability are needed. Analyses that address applicability to stochastic systems and discrete data systems are also needed. Further reduction of conservatism of the criterion for convergence derived for systems with algebraic loops (ref. 6) should be explored. The basic concept should be extended to include automatic control of convergence interval duration and other process parameters to improve performance. Implications of central versus distributed or mixed coupling architectures should be considered from viewpoints of algorithm performance and computational resource utilization.

To facilitate a multicomputer implementation, a high-level standard format for digital definition of a vector analog signal segment (function of time) needs to be chosen or created so that signal segments can be transmitted and received throughout the system. In addition, system-level command and control functions must be defined so that standard subsimulation and coupler interfaces can be developed. A single-computer multiprocessor development that takes advantage of parallel computation could advance development of requirements for a multicomputer implementation as well as facilitate a better assessment of performance. Construction of an example involving more than one computer will serve to identify a detailed set of platform- and network-specific requirements in data systems and software terms; it will also serve to explicitly demonstrate technical integrity for a multiplatform application.

10. CONCLUSIONS AND RECOMMENDATIONS

An example nonlinear, continuous simulation of satellite motion has been successfully constructed using two variations of recursive feedback to couple three separate subsimulations of orbit dynamics, attitude dynamics and control, and aerodynamics. Results have been verified by direct comparison with a conventionally constructed simulation of the same system. Each subsimulation deals with one engineering discipline, and appropriate interactions are implemented recursively at the system level. The subsimulations can, in principle, be run separately on remote and dissimilar platforms while coupling is implemented by way of network. Depending on the system-level design configuration, it is possible to run the subsimulations in parallel. The coupling signals represent physically identifiable variables associated with physical interfaces of the subsystems. The example employs three subsimulations; the method framework accommodates n. Clearly, further investigation of recursively coupled subsimulations as a systems simulation architecture is warranted. It is recommended that the present effort be expanded to include all of the future development areas mentioned above, and that longer range plans should include a pilot multisubsystem, multidiscipline, multiplatform development of a complexity level that demonstrates effectiveness and efficiency through collaboration.

APPENDIX B—FORTRAN LISTINGS

B.1 FORTRAN Listings, Including Main Program and All Subroutines, Recursive Feedback With Centralized Coupling (RFC)

```
c
c     This is FORTRAN main program "rfc.f". Development began 6/12/2000 by Doug Nixon, MSFC/TD55,
c     in support of AEI project, and the listing is contained in "aei/rfc"
c
c     The purpose is to generate the dynamic solution of three coupled subsystems (orbit dynamics,
c     attitude dynamics, and aerodynamics) by recursive feedback, which involves distributed and
c     possibly multiple methods of numerical integration. The intent is to compare results generated
c     by a standard approach using a centralized single numerical integration method. The standard
c     approach has been implemented as FORTRAN program "rku.f", and the main program is contained
c     in "aei/rku"
c

c *** Definition of the fundamental variables ************************************************************
c
c     uu(i,j) ----- System-level feedback signal. Represents the ith component at the jth time
c                   point for the total system vector feedback signal. Dimension is that of the
c                   total system, and all subsystem input vectors are contained within appropriate
c                   partitions. Data for the first subsystem is contained in the first (top)
c                   sub-column. In a more general setting, this signal would be summed with a
c                   system-level input signal vv(i,j) to form the subsystem input signals. vv(i,j)
c                   is not needed for this implementation, and has not been included.
c
c     yy(i,j) ----- System-level output signal. Represents the ith component at the jth time
c                   point for the system vector output signal. Dimension is that of the total
c                   system, and all subsystem output vectors are contained within appropriate
c                   partitions. Data for the first subsystem is contained in the first (top)
c                   partition.
c
c ********************************************************************************************************
c
c     uu1(i,j)----- First subsystem input signal. Represents the ith component at the jth time
c                   point for the vector input signal to the first (orbit dynamics) susystem,
c                   and is also the first (top) partition of uu(i,j).
c
c     uu2(i,j)----- Second subsystem input signal. Represents the ith component at the jth time
c                   point for the vector input signal to the second (attitude dynamics) subsystem,
c                   and is also the second (middle) partition of uu(i,j).
c
c     uu3(i,j)----- Third subsystem input signal. Represents the ith component at the jth time
c                   point for the vector input signal to the third (aerodynamics) subsystem, and
c                   is also the third (bottom) partition of uu(i,j).
c
c ********************************************************************************************************
cc     yy1(i,j)----- First subsystem output signal. Represents the ith component at the jth time
```

```
c                  point for the vector output signal from the first (orbit dynamics) subsystem,
c                  and is also the first (top) partition of yy(i,j).
c
c     yy2(i,j)----- Second subsystem output signal. Represents the ith component at the jth time
c                  point for the vector output signal from the second (attitude dynamics) subsystem,
c                  and is also the second (middle) partition of yy(i,j).
c
c     yy3(i,j)----- Third subsystem output signal. Represents the ith component at the jth time
c                  point for the vector output signal to the third (aerodynamics) subsystem, and is
c                  also the third (bottom)partition of yy(i,j).
c
c ***************************************************************************************************
c
c     yy1i(i) ----- Value of the output signal at the beginning of the current convergence interval
c                  for the FIRST (orbit dynamics) subsystem. Represents the ith component of the
c                  signal at the first time point, and is equivalent to yy1(i,1)
c
c     yy2i(i) ----- Value of the output signal at the beginning of the current convergence interval
c                  for the SECOND (attitude dynamics) subsystem. Represents the ith component of the
c                  signal at the first time point, and is equivalent to yy2(i,1)
c
c     yy3i(i) ----- Value of the output signal at the beginning of the current convergence interval
c                  for the THIRD (aerodynamics) subsystem. Represents the ith component of the signal
c                  at the first time point, and is equivalent to yy3(i,1)
c ***************************************************************************************************
c
c     yy1f(i) ----- Value of the output signal at the end of the current convergence interval for
c                  the FIRST (orbit dynamics) subsystem. Represents the ith component of the signal
c                  at the last time point, and is equivalent to yy1(i,ndp)
c
c     yy2f(i) ----- Value of the output signal at the end of the current convergence interval for
c                  the SECOND (attitude dynamics) subsystem. Represents the ith component of the
c                  signal at the last time point, and is equivalent to yy2(i,ndp)
c
c     yy3f(i) ----- Value of the output signal at the end of the current convergence interval for
c                  the THIRD (aerodynamics) subsystem. Represents the ith component of the vector
c                  signal yy3(i,j) at the last time point, and is equivalent to yy3(i,ndp)
c
```

```
c ******General Comments ************************************************************************
c
c     The above nomenclature has been designed to allow implementation of recursive feedback via
c     FORTRAN in such a way that independence of the subsystem simulations can be supported. The
c     partitions and contractions facilitate autonomy of the subsystem simulations while providing
c     appropriate structure for implementation of the system-level algorithm. The fact that subsystem
c     data has been placed in COMMON with the MAIN (system level) program does not necessarily mean
c     that all of that data is required or desired at the system level -- it may mean only that the
c     SUBROUTINE containing the subsystem simulation needs to have access to data that it generated
c     previously, and placing that data in COMMON is a way to provide that in FORTRAN.
c
c     While the subsystem simulation SUBROUTINES will not literally be executed in parallel, the
c     information flows in parallel paths, and the order of execution is not important. Therefore,
c     parallel execution is conceptually possible without impact to the structure of the process.
c
c     This program, which involves three subsystems, can serve as a template for implementation with any
c     number of subsystems. Use of higher order arrays to implement the general case for "n" subsystems
c     appears to serve no useful purpose in this setting at this time.
c
c     This implementation assumes that all subsystem states are needed at the system level, and transfer of
c     final conditions to initial conditions after convergence is handled at that level. For this specific
c     system, the assumption is valid; however, in general,subsystem states can exist and remain at the
c     subsystem level without the necessity of knowing them at the system level. Because of this,
c     it would be more appropriate to define and "bookkeep" initial conditions at the subsystem level for a
c     more general implementation. In the more general implementation, transfer of final conditions from
c     one convergence interval to intial conditions of the next would be handled totally at the subsystem
c     level upon receipt of "command" from the system level.

      subroutine aerocompr(vel_b,force,torque)
c
c     Developed by Doug Nixon, TD55, MSFC starting 5/26/2000 to compute
c     aerodynamic forces and torques for the "truth model" for recursive
c     feedback simulation method comparison for AEI study.
c
c     Modified by Doug Nixon, TD55, MSFC from standard/aerocomp.f starting 6/21/2000 for operation
c     in the recursive feedback setting. The attitude DCM was removed from the argument because the
c     inertial to body transformation is now performen by the system-level coupler.

c
c     rho       = Atmospheric density, kg/m**3
c     vel_b(i)  = Velocity vector in body coordinates, meters/sec
c     force(i)  = Aerodynamic force, body coordinates, newtons
c     torque(i) = Aerodynamic torque, body coordinates, newton-meters

c
      subroutine sub1(xdot,x,tau)
c
c *** This subroutine simulates three-degree-of-freedom (six-state) orbital dynamics with inverse
c     square gravity and point mass assumptions. An aerodynamic drag force f_aero(i) can be applied
c     to the satellite through common block "subsys1" variable uu1(i,j), where the following
c     definitions apply:
c
c                       x(i) = value of the ith component of the orbit state vector. This is an
c                              INPUT VARIABLE, and is not changed by this routine.
c
c                    xdot(i) = time derivative of the ith component of the orbit state vector.
c                              This is an OUTPUT VARIABLE, and is created bythis routine.
c
c                       tau = time elapsed from the beginning of the convergence interval. This
c                              is an INPUT VARIABLE, and is not changed.
c
c                   uu1(1,j) = value at the jth time point of the x-component of body force f(t)
c                              expressed in inertial coordinates. Units are newtons. This is an
```

```
c                          INPUT VARIABLE, and is not changed.
c
c                 uu1(2,j) = value at the jth time point of the y-component of body force f(t)
c                            expressed in inertial coordinates. Units are newtons. This is an
c                            INPUT VARIABLE, and is not changed.
c
c                 uu1(3,j) = value at the jth time point of the z-component of body force f(t)
c                            expressed in inertial coordinates. Units are newtons. This is an
c                            INPUT VARIABLE and is not changed.
c
c                 yy1(i,j) = value at the jth time point of the ith component of the orbit state
c                            vector. THIS VARIABLE IS NOT USED BY THIS ROUTINE.
c
c                      ndp = number of signal sample points per convergence interval, including
c                             both end points

B.2 FORTRAN Listings, Including Main Program and All Subroutines Not Previously Listed in A.1, Recursive Feedback With Distributed Coupling (RF–D)

```
c
c     This is FORTRAN MAIN program "rfd.f",and is a variation of FORTRAN main program "rfc.f".
c     Development began 6/12/2000 by Doug Nixon, MSFC/TD55, in support of AEI. The main and subprogram
c     listings are contained in "aei/rfd"
c
c     This example of simulation by recursive feedback uses distributed coupling, and convergence is
c     checked on the minimum number of signals (aerodynamic forces and torques).
c
c     The purpose is to generate the dynamic solution of three coupled subsystems (orbit dynamics,
c     attitude dynamics, and aerodynamics) by recursive feedback, which involves distributed and
c     possibly multiple methods of numerical integration. The intent is to compare results generated
c     by a standard approach using a centralized single numerical integration method. The standard
c     approach has been implemented as FORTRAN MAIN program "rku.f", and the main and subprogram listings
c     are contained in "aei/rku".

c
c     yy1f(i) ----- Value of the output signal at the end of the current convergence interval for
c                   the FIRST (orbit dynamics) subsystem. Represents the ith component of the signal
c                   at the last time point, and is equivalent to yy1(i,ndp)
c
c     yy2f(i) ----- Value of the output signal at the end of the current convergence interval for
c                   the SECOND (attitude dynamics) subsystem. Represents the ith component of the
c                   signal at the last time point, and is equivalent to yy2(i,ndp)
c
c     yy3f(i) ----- Value of the output signal at the end of the current convergence interval for
c                   the THIRD (aerodynamics) subsystem. Represents the ith component of the vector
c                   signal yy3(i,j) at the last time point, and is equivalent to yy3(i,ndp)
c
c ******General Comments ***************************************************************************
c
c     The above nomenclature has been designed to allow implementation of recursive feedback via
c     FORTRAN in such a way that independence of the subsystem simulations can be supported. Definition
c     of submatrices (partitioning) facilitates independence of the subsystem simulations while providing
c     appropriate structure for implementation of the system-level algorithm. The fact that subsystem
c     data has been placed in COMMON with the MAIN (system-level) program does not necessarily mean
c     that all of that data is required or desired at the system level -- it may mean only that the
c     SUBROUTINE containing the subsystem simulation needs to have access to data that it generated
c     previously, and placing that data in COMMON is a way to provide that in FORTRAN.
```

```
c
c     Because of the distributed coupling configuration, information flows from one sub-simulation to the
c     next in a sequential manner. The order of execution is important, and parallel execution is not
c     possible.
c
c     This implementation assumes that all subsystem states are needed at the system level, and transfer of
c     final conditions to initial conditions after convergence is handled at that level. For this specific
c     system, the assumption is valid; however, in general,subsystem states can exist and remain at the
c     subsystem level without the necessity of knowing them at the system level. Because of this,
c     it would be more appropriate to define and "bookkeep" initial conditions at the subsystem level for a
c     more general implementation. In the more general implementation, transfer of final conditions from
c     one convergence interval to intial conditions of the next would be handled totally at the subsystem
c     level upon receipt of "command" from the system level.

B.3 FORTRAN Listings, Including Main Program and All Subroutines Not Previously Listed in A.1, Unified Approach, Runge-Kutta Method (RK–U)

```
c
c *** This is main program "rku.f". Construction began 5/9/2000 by Doug Nixon, TD55, MSFC.
c     It is designed to produce a standard-method benchmark to support an evaluation of
c     recursive feedback as a multi-discipline time-domain simulation solution method.
c     The test-case is a system involving orbital mechanics, vehicle rotational dynamics
c     and aerodynamics."rku.f" is the main driver for the twelve-state dynamic system which
c     is integrated by "rksys.f", a fourth-order Runge-Kutta subroutine. "sub.f" defines the
c     dynamics in first-order state-variable form. Listings are contained in "aei/rku".

c
c *** Construction began 4/28/2000, by Doug Nixon, TD55. The purpose is to
c     supply the dynamics xdot=F(x,time) for integration by rksys, a
c     fourth-order Runge-Kutta routine. The problem is to set up a
c     standard-method simulation of a simple multidisciplined system involving
c     orbital dynamics, vehicle attitude dynamics, and aerodynamics.

c
c     The system has six degrees of freedom, or twelve states. The System states are
c     defined as follows:
c
c     Orbit States (Vehicle Position States):
c
c       x(1)=r(1): x-component of orbit radius vector in inertial coordinates,
c                  from origin of inertial system to c.m. of spacecraft (meters)
c       x(2)=r(2): y-component
c       x(3)=r(3): z-component
c
c       x(4)=v(1): x-component of spacecraft velocity vector in inertial coordinates
c                 (meters/second)
c       x(5)=v(2): y-component
c       x(6)=v(3): z-component
c
c     Vehicle Rotational States:
c
c       x(7)=phi(1): Euler angle rotation from inertial to body system, about x-axis,
c                    3rd in sequence. (radians)
c       x(8)=phi(2): About y-axis, 2nd in sequence.
c       x(9)=phi(3): About z-axis, 1st in sequence.
c
c       x(10)=omega(1):  Body rate, x-axis (radians/second)
c       x(11)=omega(2):  Body rate, x-axis
c       x(12)=omega(3):  Body rate, x-axis
c
c     Aerodynamics States:
c
c       No states are defined because the aerodynamics model has been reduced to
c       an algebraic system.

13. ABSTRACT *(Maximum 200 words)*

Conventional construction of digital dynamic system simulations often involves collecting differential equations that model each subsystem, arranging them to a standard form, and obtaining their numerical solution as a single coupled, total-system simultaneous set. Simulation by numerical coupling of independent stand-alone subsimulations is a fundamentally different approach that is attractive because, among other things, the architecture naturally facilitates high fidelity, broad scope, and discipline independence. Recursive feedback is defined and discussed as a candidate approach to multidiscipline dynamic system simulation by numerical coupling of self-contained, single-discipline subsystem simulations. A satellite motion example containing three subsystems (orbit dynamics, attitude dynamics, and aerodynamics) has been defined and constructed using this approach. Conventional solution methods are used in the subsystem simulations. Distributed and centralized implementations of coupling have been considered. Numerical results are evaluated by direct comparison with a standard total-system, simultaneous-solution approach.
